ABSTRACT

The accuracy and application of AOD products from the Moderate Resolution Imaging Spectroradiometer (MODIS) are studied in this paper by comparing with the AOD derived from the ground-based Doppler LIDAR inside the Hong Kong International Airport (HKIA). The backscattered power data of the LIDAR are used to determine the extinction coefficient profile, from which the AOD is calculated. The 1-km resolution AOD product from MODIS is found to have better correlation with the LIDAR AOD in comparison to the 10-km resolution product. Moreover, since AOD is a column-integrated quantity, its application to the monitoring of the surface visibility changes should be made with caution during the presence of elevated layers of higher aerosol concentrations. Examples of the effects of such elevated aerosol layers are studied.

1. INTRODUCTION

The MODIS AOD products are available in two resolutions over southern China, namely, the standard 10-km resolution level 2 product from National Aeronautics and Space Administration (NASA) and the 1-km resolution product based on previous field studies of AOD using sun-photometer measurements [1]. They have been widely used for the monitoring of visibility in day-to-day weather forecasting. The accuracy of these AOD products is examined in this paper by comparing with the AOD derived from Range-height Indicator (RHI) scan of a Doppler LIDAR at the Hong Kong International Airport (HKIA, location in Figure 1). This LIDAR is mainly used to make wind measurements for the monitoring of low-level windshear and turbulence. It also gives backscattered power data, which could be combined with the visibility measurements from forward scatter sensors at HKIA (locations in Figure 1) to produce the extinction coefficient profile and thus the AOD.

AOD is a column-integrated quantity. Besides the aerosol concentration near the surface, it could be affected by the presence of elevated aerosol layers within the boundary layer or even in the middle troposphere. The RHI scans of the LIDAR are able to reveal the changes of the vertical profile of aerosol concentration. The effect of elevated aerosol layer on the application of AOD to the monitoring of surface visibility is examined in this paper through examples of the LIDAR’s vertical scans.

2. CALCULATION OF LIDAR AOD

The RHI scans of the LIDAR in the azimuth angle of 258 degrees from the north are used in this study. This scan is only made up to an elevation angle of 45 degrees from the ground (Figure 2(a)). Four beams with the elevation angles between 38 and 40 degrees are used in the retrieval of the extinction coefficient profile \( \sigma(z) \). The backscattered power data and the signal-to-noise ratio (SNR) of the four beams at each height are averaged. Following [2], the average backscattered power profile with range correction \( S(r) \) (where \( r \) is the slant range from the LIDAR) are employed to retrieve the extinction coefficient profile by Klett’s algorithm:

\[
\sigma(r) = \left\{ \sigma_m + \frac{e}{k} \right\} \text{exp}\left(\frac{(S(r) - S_m)/k \right}\}
\]

for \( r \) less than a reference distance \( r_m \), \( S_m = S(r_m) \), \( \sigma_m = \sigma(r_m) \) and \( k \) a constant depending on LIDAR wavelength and the properties of the aerosol. As in the previous studies (e.g. [2]), the constant \( k \) is taken as 1. The SNR threshold for the retrieval is taken as -10.

For comparison with MODIS AOD at 550 nm, the \( \sigma(r) \) determined from Eq. (1) above is converted to the extinction coefficient profile \( \sigma'(r) \) of this visible wavelength from the wavelength of the LIDAR \( \lambda = 2022 \) nm using the following formula [2]:

\[
\sigma' = \left( \frac{55}{\lambda} \right)^{1.2} \sigma
\]

The whole extinction coefficient is then adjusted based on the visibility measured by a forward scatter sensor at HKIA [2]. In this study, the visibility data from R1C sensor (i.e. near the middle of the south runway of HKIA, location in Figure 1) are employed. Finally, the extinction coefficient profile is integrated from the ground up to a certain height \( z_{max} \) to give AOD:

\[
AOD = \frac{1}{z_{max}} \int_{0}^{z_{max}} \sigma'(z)dz
\]

It is generally observed from the RHI scans of the LIDAR that the atmosphere is basically free from aerosol above 4 km and the backscattered power greater than this height is mostly contaminated by system noise.
As such, the $z_{\text{max}}$ is taken to be 4 km in this study. As an example, the extinction coefficient profile obtained from the backscattered profile of Figure 2(a) is given in Figure 2(b). It could be seen that extinction coefficient is nearly zero at around the height of 4 km or so and the extinction coefficient at such altitudes appears to be quite noisy due to the very weak backscattered signal from the aerosol.

3. COMPARISON BETWEEN MODIS AND LIDAR AOD

The AOD values near HKIA at 10-km and 1-km resolutions are compared with that obtained from the LIDAR at about the same time in Figures 3(a) and (b) respectively. The latter turns out to have better correlation with the LIDAR AOD, with a correlation coefficient reaching 0.8. The MODIS 1-km AOD in general has larger value as the slope of the best-fit linear graph is less than unity. The reason for this over-estimation of AOD from MODIS is not clear. Similar over-estimation is also seen in the study of MODIS AOD for other coastal areas of China [3].

4. EFFECT OF ELEVATED AEROSOL LAYERS ON THE APPLICATIONS OF AOD

An elevated layer of aerosol with high concentration may appear at times higher up in the boundary layer or even in the middle troposphere. This could lead to a larger value of AOD, which may not be necessarily associated with deterioration in surface visibility. The RHI scan of the LIDAR gives the vertical distribution of backscattered power, which is related to aerosol concentration, and could be useful in the interpretation of the changes of AOD. An example is given in Figure 4. Higher concentration of aerosol appeared between 2 and 4 km above ground in the early afternoon of 1 September 2007 (Figure 4(a)). On the other hand, the boundary layer had very low concentration of aerosol only. The MODIS (Figure 4(b)) and the LIDAR AOD values over HKIA are consistent with each other – both are at the rather large value of ~0.7. The surface visibility reported at HKIA was 29 km at 1 p.m. HKT (= UTC + 8 hours) on that day. The source of the elevated aerosol layer requires further study.

Another example is given in Figure 5. From 10:30 a.m. to 2 p.m. of 5 October 2006, the AOD measured by the LIDAR increased by 74% from 0.46 to 0.8. Similar rise of AOD was also shown in the MODIS data (Figure 5(a)). However, in this period the meteorological optical range (MOR) measured by two forward scatter sensors inside HKIA, viz. R1C and R2W (locations in Figure 1) fell only slightly from ~9000 m to ~7000 m (Figure 5(a)). The 1-km resolution AOD map from MODIS depicted a significant increase of AOD over many parts of Hong Kong as well as the coastal areas on both sides of Pearl River Estuary (location in Figure 4(b)) in the course of the day (c.f. Figures 5(b) and (c)). By examining the backscattered power data from the RHI scans of the LIDAR, it appears that the AOD increase is contributed more from the rise of aerosol concentration between 1 and 2 km above ground than that near the surface (c.f. Figures 5(d) and (e)). This case again highlights the importance of examining the evolution of the vertical profile of aerosol concentration in interpreting the AOD maps of MODIS.

5. CONCLUSIONS

The accuracy and the application of MODIS AOD products are studied using the AOD derived from the RHI scans of a ground-based LIDAR. The 1-km resolution AOD values derived from MODIS are found to have better correlation with the LIDAR AOD in comparison to the standard 10-km resolution product. In the application of MODIS AOD map in the monitoring of surface visibility distribution, it is noted that elevated aerosol layers may affect the AOD values significantly and it would be useful to interpret the AOD maps together with the vertical profiles of aerosol concentration given by the LIDAR.
